ARTICLE INFO	ABSTRACT
<i>Article type:</i> Case report	Background & aim: Uterine sarcoma is a rare tumor of mesodermal origin, accounting for 2-6% of uterine malignancies. Leiomyosarcoma (LMS) has been reported in only 1% of all uterine malignancies and is regarded as the most common primary uterine sarcoma. Herein, we present a case of LMS with unusual macroscopic features.
<i>Article History:</i> Received: 7-Jan-2015 Accepted: 20-Apr-2015	Case report: The patient was a 61-years-old woman with LMS, which consisted of a large cystic mass (88×136 mm), containing six liters of brownish fluid on the right side of the pelvis and abdomen. The fundus of the uterus was ruptured by the solid part of the tumor. For treatment, total hysterectomy, salpingo-oophorectomy and the optimal resection of tumor were carried out.
<i>Key words:</i> Cystic Change Leiomyosarcoma Pelvic Neoplasm Lipid	Conclusion: Overall, the distinctive biological behavior and poor overall survival of uterine sarcoma challenge the post-operative management of this tumor. According to the one-year follow-up, the patient was disease-free. Unfortunately, no further data is available beyond this period.

Introduction

Uterine sarcoma is regarded as the most malignant uterine tumor (1, 2). The three most common histologic variants include endometrial stromal sarcoma, leiomyosarcoma (LMS) and carcinosarcoma (malignant mixed mullerian tumor) (3). However, LMS is the most common variant and is more common in younger individuals (43-53 years) (4).

The incidence of sarcomatous change in benign uterine leiomyoma is reported to range between 0.13% and 0.8% (4). A mitotic index of > 10 is indicative of severe cytologic atypia, coagulation and tumor necrosis. Also, the prognosis is poor when the tumor is disseminated out of the uterus (5). The tumor normally spreads to the myometrium, pelvic blood, lymphatic vessels, contiguous pelvic structures, the abdomen and distantly most often to the lungs (5).

Case report

A 61-year-old nulliparous woman with a large pelvic mass was referred to Ghaem Hospital, affiliated to Mashhad University of Medical Sciences. She had experienced a dull pain in the lower abdomen over the last two months. On abdominal examination, a large mass was indicated in the middle and right side of the abdomen. It was a fixed, solid, cystic mass with no ascites; the borders were not manually palpable.

According to vaginal examinations, the mass had occupied the whole pelvis, extending to the upper abdomen; also, the uterus was undistinguishable. Ultrasonography showed a heterogeneous mass (118×132×103 mm) on the fundus, suggesting uterine leiomyoma with solid (79×75 mm) and cystic components (88×136 mm).

The computed tomography (CT) scan

revealed a large heterogeneous mass (230×120×140 mm), containing solid and cystic components in the pelvis and the abdomen. The mass probably originated from the uterine or the ovaries, with no lymphadenopathy or ascites (Figure 1). The tumor marker results were as follows: cancer antigen 125 (CA-125) = 56.9, carcinoembryonic antigen (CEA) = 2.1 and serum lactate dehydrogenase (LDH) = 670.

Intra-operatively, a large, lobulated, solid, cystic mass was detected, which occupied the pelvis and the abdomen and extended to the upper umbilicus with adhesions to the abdominal wall, fascia, bowel and peritoneum. The cystic component had a very thin wall and was extending to the upper abdomen on the right side.

The thin wall of the cystic component was ruptured and six liters of brownish fluid was evacuated. The fundus of the uterus was completely ruptured by the necrotic tumor (Figure 2). The ovaries and fallopian tubes were

apparently normal and instant pathologic report indicated LMS.

For treatment, total hysterectomy, salpingo-oophorectomy and the optimal resection of tumoral parts were carried out. Pathologic response indicated high-grade LMS of the uterus, which extended to all layers of the uterine wall and consisted of smooth muscle bundles with extensive necrosis.

LMS is composed of malignant uterine smooth muscle cells. It also involves the omentum, bowel and peritoneum. The cells are elongated with tapered ends. At a microscopic level, LMS may histologically resemble normal uterine musculature. The less differentiated the sarcoma is, the less it resembles a leiomyoma. As the cellularity increases, nuclear atypia increases, cytoplasm becomes more eosinophilic and the number of giant cells rises.

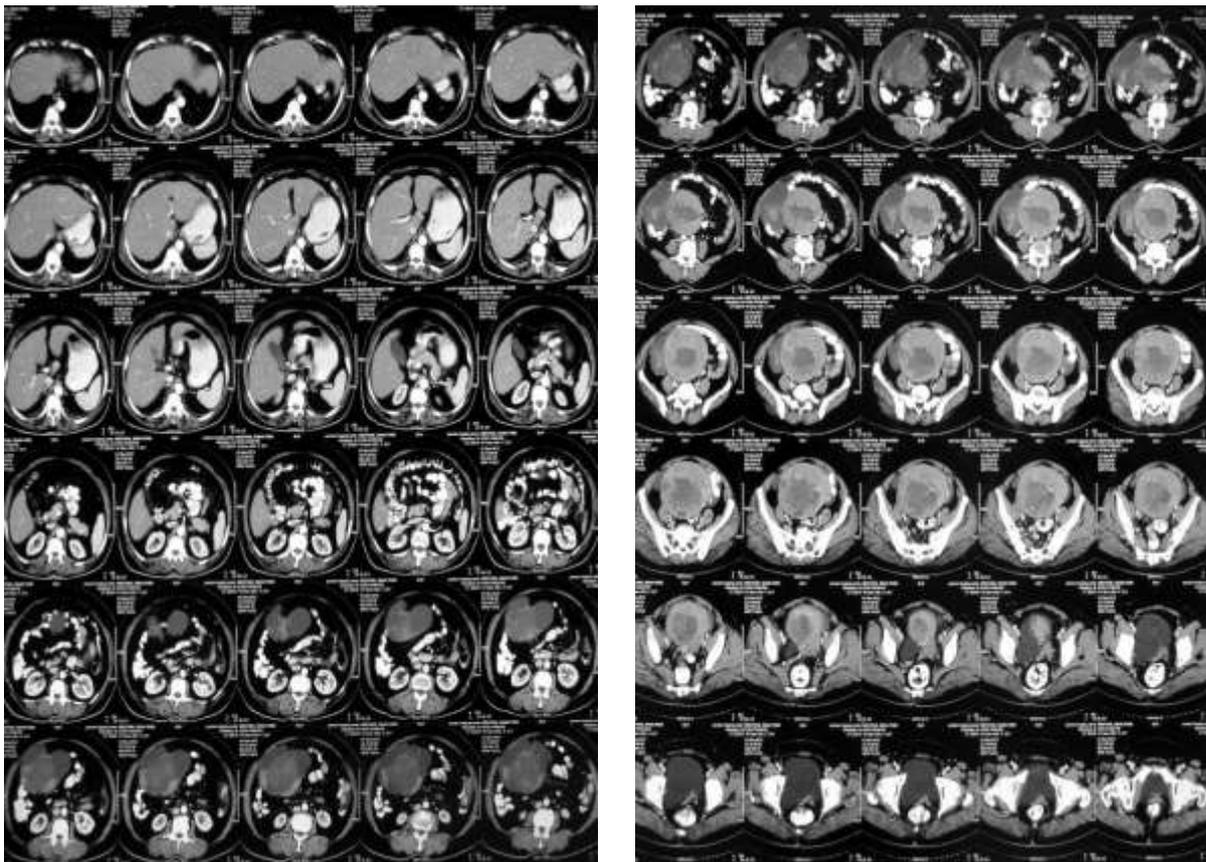

Figure 1. CT scan showed a large heterogeneous mass in the pelvis and the abdomen

Figure 2. The macroscopic appearance of the tumor indicated a multilocular cystic tumor with solid components

On the first and eighth days, chemotherapy with gemcitabine (900 mg/m²) was performed. Chemotherapy continued with docetaxel (100 mg/m²) on the eighth day and every 21 days after the operation for six cycles. According to the one-year follow-up, the patient was disease-free. Unfortunately, no further information is at hand beyond this period.

Discussion

LMS is a rare uterine neoplasm with a poor prognosis (6). The usual appearance of LMS is a soft, fleshy, ill-defined mass with hemorrhage and necrosis in the macroscopic tumor section (6). In the present case, LMS was predominantly a large cystic mass. It should be mentioned that the symptoms including vaginal bleeding, pelvic pain/pressure and abdomino-pelvic mass do not normally last long (mean duration = 6 months) (7).

The present case had experienced dull pain over the last two months, without any other symptoms. According to sonography and CT scan, the origin of the mass was not exactly determined, although the uterine or the ovaries (or both) were suspected.

Although ultrasonography is the most common imaging modality in gynecology, different new modalities have been introduced for improving the preoperative diagnosis of pelvic masses, especially pelvic sarcoma.

Generally, CT scan, magnetic resonance imaging (MRI), 2-Deoxy-2-[18F] fluoro-D-glucose positron emission tomography (PET) and fluorodeoxyglucose PET are the most important modalities (8-10).

LMS tends to involve cystic changes and be more heterogeneous than most leiomyomas (11). However, in this case report, an unusually large cyst was found. In fact, LMS could be included in the differential diagnosis of large pelvic cystic tumors. Considering this unusual appearance, the present case was reported.

Elevated serum LDH has been suggested as a marker of LMS, although it has not been independently confirmed (12); in the present case, serum LDH titer was high (670 U/L). The distinctive biological behavior and poor overall survival of uterine sarcoma challenge the post-operative management of this tumor. However, chemotherapy regimen has been suggested to be useful (13, 14). In this patient, gemcitabine, along with docetaxel, was prescribed for chemotherapy. Several studies have confirmed that radiotherapy does not increase the quality of life and survival in LMS patients (15, 16).

Conflict of interest

The authors declare no conflict of interest.
